Compressional sound velocity of hexagonal close-packed iron up to 163 GPa and 3000 K

Seismological data reveal important physical properties of Earth’s core, such as density and elasticity. Earth’s core is mainly composed of iron (Fe), and the stable crystal structure of Fe under the inner core conditions is the hexagonal close-packed (hcp) structure. The density of the inner core based on the Preliminary Reference Earth Model (PREM) [1], which was proposed by using seismological data, is about 2–5% less than that of hcp-Fe (a core density deficit), and it is accepted that the inner core consists of iron and light elements, such as silicon, sulfur, oxygen, hydrogen, and carbon.

To constrain the sound velocity of the inner core and the abundances of light elements, the sound velocities of Fe and Fe alloys have been measured at high pressures by inelastic X-ray scattering (IXS) and nuclear resonant inelastic X-ray scattering (NRIXS). However, due to experimental difficulties, sound velocity measurements with static compression above 2000 K have never been reported. Some previous studies of IXS using external heated DAC showed a small temperature effect on the velocity; however, the maximum temperature range was limited to around 1100 K and the temperature dependence is still not sufficiently clear to discuss the Earth’s core.

It is necessary to determine the sound velocity of hcp-Fe at high temperatures in order to quantitatively clarify the difference in the sound velocity between Earth’s inner core and hcp-Fe. An important point is that the constituents of the Earth’s inner core should fill the gap of both the density and the sound velocity between hcp-Fe and those in seismological models, such as PREM, under the inner core conditions. Here, we report the compressional sound velocity ($V_p$) of hcp-Fe up to 163 GPa and 3000 K (Fig. 1) based on a combination of laser-heated DAC [2] and IXS measurements at SPring-8 BL35XU [3].

$V_p$ for hcp-Fe as a function of density is shown in Fig. 2, together with data obtained at 300 K [4] and shock compression data [5]. These data were fitted by allowing the coefficients in the linear $\rho - V_p$ relation to vary with the temperature, so that Birch’s law is preserved at any fixed temperature. A good fit to the data is possible by assuming a first order and linear temperature dependence of the coefficients. The dependence was parameterized as

$$V_p (\rho, T) = M \rho + B + A (T - T_0) (\rho - \rho^*) \quad (1).$$

We choose $T_0$ to be 300 K; thus, $M$ and $B$ are the coefficients of Birch’s law at room temperature, while $A$ and $\rho^*$ indicate the temperature dependence. Fitting our data combined with room temperature data [3] and shock compression data along the Hugoniot [4] gives $M = 1.160 \pm 0.025$, $B = -3.43 \pm 0.29$, $A = 7.2 \pm 3.6 \times 10^{-5}$, and $\rho^* = 14.2 \pm 1.5$.

To demonstrate the difference in density and $V_p$ between hcp-Fe and Earth’s inner core, we compare the $\rho - V_p$ characteristics under the conditions of the inner core boundary (ICB). The recent arguments on the thermal state of the outer core based on melting experiments of iron-light element systems suggest that the temperature at the ICB is around 5500 K. $V_p$ at 330 GPa and 5500 K can be calculated by using the density of hcp-Fe and the temperature dependence of Birch’s law given in Eq. 1. The obtained $V_p$ for hcp-Fe at 5500 K is shown as a function of density in Fig. 3(a) and compared with PREM in the inner core [1]. The density and compressional velocity of hcp-Fe under the ICB conditions (330 GPa and 5500 K) are calculated to be 13.42 g/cm$^3$ and 11.85 km/s, respectively. Thus, both the density and $V_p$ for hcp-Fe are higher than those in PREM, which are 12.76 g/cm$^3$ and 11.03 km/s at the ICB, respectively. The Earth’s inner core has a 4–5% smaller density and 7% smaller $V_p$ than hcp-Fe. Thus, we can conclude that the light elements or the combination of the light elements and nickel in the inner core decreases both the density and compressional velocity of hcp-Fe simultaneously under the inner core conditions.

The sound velocity and density of Fe and Fe alloys have been experimentally measured in order to demonstrate the effect of light elements on the properties of iron. Figure 3(b) shows the $\rho - V_p$ plots of iron-light element systems suggesting that the temperature

\[ Q = 8.48 \text{ nm}^{-1} \]

163 GPa
3000 K

Elastic peak

Diamond (TA)

hcp-Fe (LA)
